Abstract. Motivated from drawing route sketches, we consider the following path schematization problem. We are given a simple embedded polygonal path $P = (v_1, \dots, v_n)$ and a set \mathcal{C} of admissible edge orientations including the coordinate axes. The problem is to redraw P schematically such that all edges are drawn as line segments that are parallel to one of the specified orientations. We also require that the path preserves the orthogonal order and that it remains intersection-free. Finally, we want the drawing to maximize the number of edges having their preferred edge direction and to minimize the path length.

In this paper we first present an efficient two-step approach for schematizing *monotone* paths. It consists of an $O(n^2)$ -time algorithm to assign edge directions optimally and a subsequent linear program to minimize the path length. In order to schematize non-monotone paths we propose a heuristic that first splits the input into k monotone subpaths and then combines the optimal embeddings of the monotone subpaths into a single, intersection-free embedding of the initial path in $O(k^2 + n)$ time.

1 Introduction

Simplification and schematization of map objects are well-known operators in cartographic *generalization*, i. e., the process to adapt map content to its scale and use. Simplification usually reduces unnecessary complexity, e. g., by removing extraneous vertices of a polygonal line while still maintaining its overall appearance. Schematization, however, may abstract more drastically from geographic reality as long as the intended map use allows for it. Public transport maps are good examples of schematization, where edge orientations are limited to a small number of slopes and edge lengths are no longer drawn to scale [10]. In spite of all distortions, such maps usually work well.

In this paper we consider a path schematization problem that is motivated from visualizing routes in road networks. Routes typically begin and end in residential or commercial areas, where roads are mostly used only for short distances of a few meters up to a few hundred meters. As soon as the route leaves the city limits, however, country roads and highways tend to be used for distances

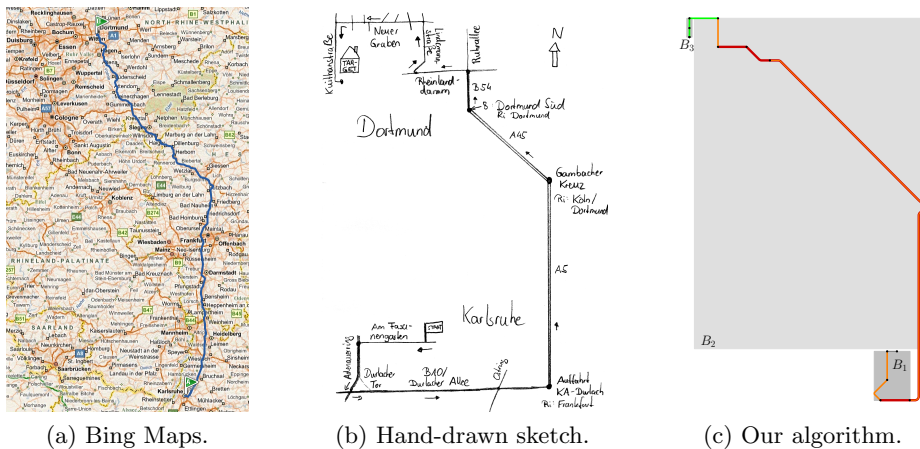

Fig. 1: Comparison of different methods for drawing a route.

ranging from a few up to hundreds of kilometers. Moreover, optimal routes tend to follow a general driving direction and deviations from this direction are rare.

Commercial route planners typically present driving directions for such routes as a graphical overview of the route highlighted in a traditional road map (see Fig. 1a) in combination with a textual step-by-step description. The overview map is good for giving a general idea of the route, but due to its small scale it often does not succeed in showing details of the route, in particular for short roads in the vicinity of start and destination and off the main highways. Textual descriptions are accurate when used at the right moment but there is a high risk of loss of context. On the other hand, a manually drawn route sketch often shows the whole route in a single picture, where each part of the route has its own appropriate scale: important turning points along the route and short residential roads are enlarged while long stretches of highways and country roads are shortened. Edges are often aligned with a small set of orientations rather than being geographically accurate [12]. Figure 1b gives an example. In spite of the cartographic error, such route sketches are often easier to read than textual descriptions and traditional road maps—at least if the user’s *mental* or *cognitive map*, i. e., a rough idea of the geographic reality, is preserved [8,11].

We formalize the application problem of drawing route sketches as a geometric path schematization problem. Given a plane embedding of a path P , the goal is to find a short *schematic* embedding of P that is as similar to the input embedding as possible but uses only a restricted set \mathcal{C} of edge orientations. We call such an embedding \mathcal{C} -oriented. For our application of route sketches, the path P is given by n important points along the route. These important points can be turns, important junctions, highway ramps, etc.

Related Work. Similar path schematization problems have been studied before. Neyer [9] proposed an algorithm to solve the \mathcal{C} -oriented line simplification

problem, where a \mathcal{C} -oriented simplification Q of a polygonal path P is to be computed that uses a minimum number of edges. Furthermore, Q must have Fréchet distance at most ε from P . For a constant-size set \mathcal{C} the algorithm has a running time of $O(kn^2 \log n)$, where n is the number of vertices of P and k is the number of vertices of Q . Merrick and Gudmundsson [7] studied a slightly relaxed version of the same problem and gave an $O(n^2|\mathcal{C}|^3)$ -time algorithm to compute a \mathcal{C} -oriented simplification of P that is within Hausdorff distance at most ε of P . Agrawala and Stolte [1] designed a system called *LineDrive* that uses heuristic methods based on simulated annealing in order to render route maps similar to hand-drawn sketches. While their system allows distortion of edge lengths and angles, the resulting paths are neither \mathcal{C} -oriented nor can hard quality guarantees be given. They did, however, implement and evaluate the system in a study that showed that users generally preferred LineDrive route maps over traditional route maps. Brandes and Pampel [2] studied the path schematization problem in the presence of orthogonal order constraints [8] in order to preserve the mental map. They showed that deciding whether a rectilinear schematization of a path P exists that preserves the orthogonal order of P is NP-hard. They also showed that schematizing a path using arbitrarily oriented unit-length edges is NP-hard.

Our Contribution. Due to the NP-hardness of rectilinear path schematization [2], we cannot hope for an algorithm that solves the general \mathcal{C} -oriented path schematization problem efficiently. Rather, we present an efficient algorithm to solve the corresponding *monotone* path schematization problem, in which the input is restricted to x - or y -monotone paths (Section 3). The algorithm consists of two steps: First, we compute in quadratic time a \mathcal{C} -oriented schematization of the input path that preserves the orthogonal order of the input and has minimum schematization cost (to be defined). Next, we use a linear program to minimize the total path length such that the schematization cost remains minimum.

In order to use this algorithm to generate route sketches for non-monotone input paths, we present a three-step heuristic approach (Section 4): We first split the path in linear time into a minimum number k of monotone subpaths, then we use the previous algorithm to optimally schematize each subpath, and finally we combine the k schematized subpaths into a single intersection-free route sketch for the non-monotone input path in $O(k^2 + n)$ time. Note that routes in practice tend to follow a general direction given by the straight line connecting start and destination. Thus if a path is not monotone itself, then it usually consists of a very small number of monotone subpaths (see the example in Fig. 1c, which decomposes into three monotone subpaths).

For omitted proofs and details we refer to the full version of this paper [4].

2 Preliminaries

Let $P = (v_1, \dots, v_n)$ be a path with edges $v_i v_{i+1}$ for $1 \leq i \leq n-1$. For a vertex v and an edge e of P we say $v \in P$ and $e \in P$. A *plane embedding* $\pi : P \rightarrow \mathbb{R}^2$ maps each vertex $v_i \in P$ to a point $\pi(v_i) = (x_\pi(v_i), y_\pi(v_i))$ and each edge $uv \in P$ to the line segment $\pi(uv) = \overline{\pi(u)\pi(v)}$ such that π is a simple polygonal path with

vertex set $\{\pi(v_1), \dots, \pi(v_n)\}$. We denote the length of an edge e in π as $|\pi(e)|$. An *embedded path* is a pair (P, π) of a path P and a plane embedding π of P . Let $\mathcal{C} = \{\gamma_1, \dots, \gamma_k\}$ be a set of angles w. r. t. the x -axis that represents the admissible edge orientations. We require that $\{0^\circ, 90^\circ, 180^\circ, 270^\circ\} \subseteq \mathcal{C}$. Reasonable sets of edge directions for route sketches are, e. g., multiples of 30 or 45 degrees. A plane embedding π of a path is called \mathcal{C} -*oriented* if the direction of each edge in π corresponds to an angle in \mathcal{C} . For an embedding π of P and an edge $e \in P$ we denote by $\alpha_\pi(e)$ the angle of $\pi(e)$ w. r. t. the x -axis. For the input embedding π , we similarly denote by $\omega_{\mathcal{C}}(e)$ the *preferred angle* $\gamma \in \mathcal{C}$, i. e., the angle in \mathcal{C} that is closest to $\alpha_\pi(e)$. For a \mathcal{C} -oriented embedding ρ of P and an edge $e \in P$ the *direction cost* $c_\rho(e)$ captures by how much the angle $\alpha_\rho(e)$ deviates from $\omega_{\mathcal{C}}(e)$. Then, we define the *schematization cost* $c(\rho)$ as $c(\rho) = \sum_{e \in P} c_\rho(e)$.

Following Misue et al. [8], we say that an embedding ρ of a path P preserves the *orthogonal order* of another embedding π of P if for any two vertices v_i and $v_j \in P$ we have $x_\pi(v_i) \leq x_\pi(v_j)$ if and only if $x_\rho(v_i) \leq x_\rho(v_j)$ and $y_\pi(v_i) \leq y_\pi(v_j)$ if and only if $y_\rho(v_i) \leq y_\rho(v_j)$. In other words, any two vertices keep their above-below and left-right relationship.

3 Monotone Path Schematization

In this section, we solve the monotone \mathcal{C} -oriented path schematization problem:

Problem 1. Given an embedded x - or y -monotone path (P, π) , a set \mathcal{C} of edge orientations and a minimum length $\ell_{\min}(e)$ for each edge $e \in P$, find a plane \mathcal{C} -oriented embedding ρ of P that

- (i) preserves the orthogonal order of the input embedding π ,
- (ii) minimizes the schematization cost $c(\rho)$,
- (iii) respects the individual minimum edge lengths $|\rho(e)| \geq \ell_{\min}(e)$, and
- (iv) minimizes the total path length $\sum_{e \in P} |\rho(e)|$.

Note that schematization cost and total path length are two potentially conflicting optimization criteria. Primarily, we want to find an embedding that minimizes the schematization cost (see Section 3.1). In a second step, we minimize the total path length of that embedding without changing the previously assigned edge directions (see Section 3.2). The rationale for preserving the orthogonal order of the input is to maintain the user’s mental map [5,2,8].

3.1 Minimizing the Schematization Cost

The goal in the first step of our algorithm is to find an embedding with minimum schematization cost. Here we assume that the input path (P, π) is x -monotone; y -monotone paths are schematized analogously. We assign the preferred angle $\omega_{\mathcal{C}}(e) = \gamma$ to each edge $e \in P$, where $\gamma \in \mathcal{C}$ is the angle closest to $\alpha_\pi(e)$. This takes constant time per edge. It could, however, result in the following conflict.

Consider two subsequent edges e_1, e_2 with $\{\omega_C(e_1), \omega_C(e_2)\} = \{90^\circ, 270^\circ\}$. Assigning such preferred angles would result in an overlap of e_1 and e_2 . In this case, we either set $\omega_C(e_1)$ or $\omega_C(e_2)$ to its next best value, depending on which edge is closer to it. This neither changes the solution nor creates new conflicts since in a plane embedding not both edges can have their preferred direction.

The output embedding ρ must be x -monotone, too, as it preserves the orthogonal order of π . So we can assume that $P = (v_1, \dots, v_n)$ is ordered from left to right in both embeddings. Let ρ' be any orthogonal-order preserving embedding of P . We start with the observation that in ρ' every edge $e = v_i v_{i+1}$ with $\omega_C(e) \neq 0^\circ$ and $y_{\rho'}(v_i) \neq y_{\rho'}(v_{i+1})$ can be embedded with its preferred direction $\alpha_{\rho'}(e) = \omega_C(e)$. This is achieved by horizontally shifting the whole embedding ρ' right of $x_{\rho'}(v_{i+1})$ (including v_{i+1}) to the left or to the right until the slope of e satisfies $\alpha_{\rho'}(e) = \omega_C(e)$. Due to the x -monotonicity of P no other edges are affected by this shift. We now group all edges $e = uv$ of P into four categories:

1. if $\omega_C(e) = 0^\circ$ and $y_\pi(u) \neq y_\pi(v)$ then e is called horizontal edge (or *h-edge*);
2. if $y_\pi(u) = y_\pi(v)$ then e is called strictly horizontal edge (or *sh-edge*);
3. if $\omega_C(e) \neq 0^\circ$ and $x_\pi(u) \neq x_\pi(v)$ then e is called vertical edge (or *v-edge*);
4. if $x_\pi(u) = x_\pi(v)$ then e is called strictly vertical edge (or *sv-edge*).

Using these categories, we define the direction cost as follows. All edges e with $\alpha_\rho(e) = \omega_C(e)$ are drawn according to their preferred angle and we assign the cost $c_\rho(e) = 0$. For all edges e with $\alpha_\rho(e) \neq \omega_C(e)$ we assign the cost $c_\rho(e) = 1$. An exception are the sh- and sv-edges, which must be assigned their preferred angle due to the orthogonal ordering constraints. Consequently, we set $c_\rho(e) = \infty$ for any sh- or sv-edge e with $\alpha_\rho(e) \neq \omega_C(e)$. Using the above horizontal shifting argument, the cost $c_\rho(e)$ of any edge e depends only on the vertical distance between its endpoints. So, the schematization cost of an x -monotone embedding ρ is already fully determined by assigning y -coordinates $y_\rho(v)$ to all v of P .

In order to determine an embedding with minimum schematization cost we define $m \leq n - 1$ closed and vertically bounded horizontal strips s_1, \dots, s_m induced by the set $\{y = y_\pi(v_i) \mid 1 \leq i \leq n\}$ of horizontal lines through the vertices of (P, π) . Let these strips be ordered from top to bottom as shown in Fig. 2a. Furthermore we define a dummy strip s_0 above s_1 that is unbounded on its upper side. We say that an edge $e = uv$ *crosses* a strip s_i and conversely that s_i *affects* e if $\pi(u)$ and $\pi(v)$ lie on opposite sides of s_i . In fact, to determine the cost of an embedding ρ it is enough to know for each strip whether it has a positive height or not. Our algorithm will assign a symbolic height $h(s_i) \in \{0, 1\}$ to each strip s_i such that the schematization cost is minimum. Note that sh-edges do not cross any strip but rather coincide with some strip boundary. Hence all sh-edges are automatically drawn horizontally and have no direction costs. We can therefore assume that there are no sh-edges in (P, π) .

Let $S[i, j] = \bigcup_{k=i}^j s_k$ be the union of the strips s_i, \dots, s_j and let $\mathcal{I}(i, j)$ be the subinstance of the path schematization problem containing all edges that lie completely within $S[i, j]$. Note that $\mathcal{I}(1, m)$ corresponds to the original instance (P, π) , whereas in general $\mathcal{I}(i, j)$ is no longer a connected path but a collection of edges. The following lemma is a key to our algorithm.

Lemma 1. *Let $\mathcal{I}(i, j)$ be a subinstance of the path schematization problem and let $s_k \subseteq S[i, j]$ be a strip for some $i \leq k \leq j$. If we assign $h(s_k) = 1$ then $\mathcal{I}(i, j)$ decomposes into the two independent subinstances $\mathcal{I}(i, k-1)$ and $\mathcal{I}(k+1, j)$. The direction costs of all edges affected by s_k are determined by setting $h(s_k) = 1$.*

Proof. We first show that the cost of any edge $e = uv$ that crosses s_k is determined by setting $h(s_k) = 1$. Since u and v lie on opposite sides of s_k we know that $y_\rho(u) \neq y_\rho(v)$. So if e is a v- or sv-edge it can be drawn with its preferred angle and $c_\rho(e) = 0$ regardless of the height of any other strip crossed by e . Conversely, if e is an h-edge it is impossible to draw e horizontally regardless of the height of any other strip crossed by e and $c_\rho(e) = 1$. Recall that sh-edges do not cross any strips. Assume that $k = 2$ in Fig. 2a and we set $h(s_2) = 1$; then edges v_3v_4 and v_5v_6 cross strip s_2 and none of them can be drawn horizontally.

The remaining edges of $\mathcal{I}(i, j)$ do not cross s_k and are either completely contained in $S[i, k-1]$ or in $S[k+1, j]$. Since the costs of all edges affected by s_k are independent of the heights of the remaining strips in $S[i, j] \setminus \{s_k\}$, we solve the two subinstances $\mathcal{I}(i, k-1)$ and $\mathcal{I}(k+1, j)$ independently, see Fig. 2a. \square

Our Algorithm. We can now describe our algorithm for assigning symbolic heights to all strips s_1, \dots, s_m such that the induced embedding ρ has minimum schematization cost. The main idea is to recursively compute an optimal solution for each instance $\mathcal{I}(1, i)$ by finding the best $k \leq i$ such that $h(s_k) = 1$ and $h(s_j) = 0$ for $j = k+1, \dots, i$. By using dynamic programming we can compute an optimal solution for $\mathcal{I}(1, m) = (P, \pi)$ in $O(n^2)$ time.

Let $C(k, i)$ for $1 \leq k \leq i$ denote the schematization cost of all edges in the instance $\mathcal{I}(1, i)$ that either cross s_k or have both endpoints in $S[k+1, i]$ if we set $h(s_k) = 1$ and $h(s_j) = 0$ for $j = k+1, \dots, i$. Let $C(0, i)$ denote the schematization cost of all edges in the instance $\mathcal{I}(1, i)$ if $h(s_j) = 0$ for all $j = 1, \dots, i$. We use an array T of size $m+2$ to store the minimum schematization cost $T[i]$ of the instance $\mathcal{I}(1, i)$. Then $T[i]$ is recursively defined as follows

$$T[i] = \begin{cases} \min_{0 \leq k \leq i} (T[k-1] + C(k, i)) & \text{if } 1 \leq i \leq m \\ 0 & \text{if } i = 0 \text{ or } i = -1. \end{cases} \quad (1)$$

Together with $T[i]$ we store the index k that achieves the minimum value in the recursive definition of $T[i]$ as $k[i] = k$. This allows us to compute the actual strip

Fig. 2: Example of (a) an x -monotone embedded input path (P, π) and (b) a \mathcal{C} -oriented (multiples of 45°) orthogonal-order preserving output path (P, ρ) .

heights using backtracking. Note that $T[m] < \infty$ since, e. g., the solution that assigns height 1 to every strip induces cost 0 for all sv-edges. Obviously, we need $O(m)$ time to compute each entry in T assuming that the schematization cost $C(k, i)$ is available in $O(1)$ time. This yields a total running time of $O(m^2)$.

The next step is to precompute the schematization cost $C(k, i)$ for any $0 \leq k \leq i \leq m$. This cost is composed of two parts. The first part is the schematization cost of all edges that are affected by s_k . As observed in Lemma 1, all v- and sv-edges crossing s_k have no cost. On the other hand, every h-edge that crosses s_k has cost 1. So we need to count all h-edges in $\mathcal{I}(1, i)$ that cross s_k . The second part is the cost of all edges that are completely contained in $S[k+1, i]$. Since $h(s_{k+1}) = \dots = h(s_i) = 0$ we observe that any h-edge in $S[k+1, i]$ is drawn horizontally at no cost. In contrast, no v- or sv-edge e in $S[k+1, i]$ attains its preferred angle $\omega_C(e) \neq 0^\circ$. Hence every v-edge in $S[k+1, i]$ has cost 1 and every sv-edge has cost ∞ . So we need to check whether there is an sv-edge contained in $S[k+1, i]$ and if this is not the case count all v-edges contained in $S[k+1, i]$.

In order to efficiently compute the values $C(k, i)$ we assign to each strip s_i three sets of edges. Let $H(i)$ (resp. $V(i)$ or $SV(i)$) be the set of all h-edges (resp. v-edges or sv-edges) whose lower endpoint lies on the lower boundary of s_i . We can compute $H(i)$, $V(i)$, and $SV(i)$ in $O(n)$ time for all strips s_i . Then for $k \leq i$ the number of h-edges in $H(i)$ that cross s_k is denoted by $\sigma_H(k, i)$ and the number of v-edges in $V(i)$ that do *not* cross s_k is denoted by $\sigma_V(k, i)$. Finally, let $\sigma_{SV}(k, i)$ be the number of sv-edges in $SV(i)$ that do *not* cross s_k . This allows us to recursively compute the values $C(k, i)$, $0 \leq k \leq i \leq m$:

$$C(k, i) = \begin{cases} \infty & \text{if } \sigma_{SV}(k, i) \geq 1 \\ C(k, i-1) + \sigma_H(k, i) + \sigma_V(k, i) & \text{if } k \leq i-1 \\ \sigma_H(k, k) & \text{if } k = i. \end{cases} \quad (2)$$

Since each edge appears in exactly one of the sets $H(i)$, $V(i)$, or $SV(i)$ for some i it is counted towards at most m values $\sigma_H(\cdot, i)$, $\sigma_V(\cdot, i)$, or $\sigma_{SV}(\cdot, i)$, respectively. Thus for computing all these values we need $O(nm)$ time. The values $C(k, i)$ can be precomputed in $O(m^2)$ time and require a table of size $O(m^2)$. This can be reduced, however, to $O(m)$ space as follows. We compute and store the values $T[i]$ in the order $i = 1, \dots, m$. For computing the entry $T[i]$ we use only the values $C(\cdot, i)$. To compute the next entry $T[i+1]$ we first compute the values $C(\cdot, i+1)$ from $C(\cdot, i)$ and then discard all $C(\cdot, i)$. This reduces the required space to $O(m)$. Since $m \leq n$ we obtain

Theorem 1. *Our algorithm to compute the array T of path schematization costs requires $O(n^2)$ time and $O(n)$ space.*

It remains to determine the strip height assignments corresponding to the schematization cost in $T[m]$ and show the optimality of that solution. We initialize all heights $h(s_i) = 0$ for $i = 1, \dots, m$. Recall that $k[i]$ equals the index k that minimized the value $T[i]$ in (1). To find all strips with height 1 we initially set $j = m$. If $k[j] = 0$ we stop; otherwise we assign $h(s_{k[j]}) = 1$, update $j = k[j] - 1$,

and continue with the next index $k[j]$ until we hit $k[j] = 0$ for some j encountered in this process. Let ρ be the \mathcal{C} -oriented embedding of P induced by this strip height assignment, see Fig. 2b. We now show the optimality of ρ in terms of the schematization cost.

Theorem 2. *Given an x -monotone embedded path (P, π) and a set \mathcal{C} of edge orientations, our algorithm computes a plane \mathcal{C} -oriented embedding ρ of P that preserves the orthogonal order of π and has minimum schematization cost $c(\rho)$.*

Proof. Since the path is x -monotone and by construction there are no two adjacent edges with preferred angles 90° and 270° the embedding ρ is plane. By construction, ρ is \mathcal{C} -oriented and it also preserves the orthogonal order of π since the x - and y -ordering of the vertices of P is not altered.

We show that ρ has minimum schematization cost by structural induction. For an instance with a single strip s there are only two possible solutions of which our algorithm chooses the better one. The induction hypothesis is that our algorithm finds an optimal solution for any instance with at most m strips. So let's consider an instance with $m+1$ strips and let ρ' be any optimal plane \mathcal{C} -oriented and orthogonal-order preserving solution for this instance. If all strips s in ρ' have height $h(s) = 0$ then by (1) it holds that $c(\rho) = T[m+1] \leq C(0, m+1) = c(\rho')$. Otherwise, let k be the largest index for which $h(s_k) = 1$ in ρ' . When computing $T[m+1]$ our algorithm also considers the case where s_k is the bottommost strip of height 1, which has a cost of $T[k-1] + C(k, m+1)$. If $h(s_k) = 1$ we can split the instance into two independent subinstances to both sides of s_k by Lemma 1. The schematization cost $C(k, m+1)$ contains the cost for all edges that cross s_k and this cost is obviously the same as in ρ' since $h(s_k) = 1$ in both embeddings. Furthermore, $C(k, m+1)$ contains the cost of all edges in the subinstance below s_k , for which we have by definition $h(s_{k+1}) = \dots = h(s_{m+1}) = 0$. Since k is the largest index with $h(s_k) = 1$ in ρ' this is also exactly the same cost that this subinstance has in ρ' . Finally, the independent subinstance above s_k has at most m strips and hence $T[k-1]$ is the minimum cost for this subinstance by induction. It follows that $c(\rho) = T[m+1] \leq T[k-1] + C(k, m+1) \leq c(\rho')$. This concludes the proof. \square

3.2 Minimizing the Path Length

In the first step of our algorithm we obtained a \mathcal{C} -oriented and orthogonal-order preserving embedding ρ with minimum schematization cost for an embedded input path (P, π) . The strip heights assigned in that step are either 0 or 1, but this does not yet take into account the actual edge lengths induced by ρ . So in the second step, we adjust ρ such that the total path length is minimized and $|\rho(e)| \geq \ell_{\min}(e)$ for all $e \in P$. We make sure, however, that the orthogonal order and all angles $\alpha_\rho(e)$ remain unchanged.

Note that we can immediately assign the minimum length $\ell_{\min}(e)$ to every horizontal edge e in the input (P, ρ) by horizontally shifting the subpaths on both sides of e . For any non-horizontal edge $e = uv$ the length $|\rho(e)|$ depends only

on the vertical distance $\Delta_y(e) = |y_\rho(u) - y_\rho(v)|$ of its endpoints and the angle $\alpha_\rho(e)$. In fact, $|\rho(e)| = \Delta_y(e) / \sin \alpha_\rho(e)$. So in order to minimize the path length we need to find y -coordinates for all strip boundaries such that $\sum_{e \in P} |\rho(e)|$ is minimized. These y -coordinates together with the given angles for all edges $e \in P$ induce the corresponding x -coordinates of all vertices of P .

So for each strip s_i ($i = 0, \dots, m$) let y_i denote the y -coordinate of its lower boundary. For every edge $e \in P$ let $t(e)$ and $b(e)$ denote the index of the top- and bottommost strip, respectively, that is crossed by e . Then $\Delta_y(e) = y_{t(e)-1} - y_{b(e)}$. We propose the following linear program (LP) to minimize the path length of a given \mathcal{C} -oriented embedded path (P, ρ) .

$$\begin{aligned} \text{Minimize} \quad & \sum_{e \in P, \alpha_\rho(e) \neq 0^\circ} \left[\frac{1}{\sin \alpha_\rho(e)} \cdot (y_{t(e)-1} - y_{b(e)}) \right] \\ \text{subject to} \quad & y_{t(e)-1} - y_{b(e)} \geq \sin \alpha_\rho(e) \cdot \ell_{\min}(e) \quad \forall e \in P, \alpha_\rho(e) \neq 0^\circ \\ & y_{i-1} - y_i \geq 0 \quad \forall s_i \text{ with } h(s_i) = 1 \\ & y_{i-1} - y_i = 0 \quad \forall s_i \text{ with } h(s_i) = 0 \end{aligned}$$

We assign to all vertices their corresponding y -coordinates from the solution of the LP. In a left-to-right pass over P we compute the correct x -coordinates of each vertex v_i from the vertical distance to its predecessor vertex v_{i-1} and the angle $\alpha_\rho(v_{i-1}v_i)$. This yields a modified embedding ρ' that satisfies all our requirements: the path length is minimized; the orthogonal order is preserved due to the x -monotonicity of P and the constraints in the LP to maintain the y -order; by construction the directions of all edges are the same in ρ and ρ' ; no edge e is shorter than its minimum length $\ell_{\min}(e)$. Hence, ρ' solves Problem 1 and together with Theorems 1 and 2 we obtain

Theorem 3. *The monotone \mathcal{C} -oriented path schematization problem (Problem 1) for a monotone input path of length n can be solved by an $O(n^2)$ -time algorithm to compute an embedding ρ of minimum schematization cost followed by solving a linear program to minimize the path length of ρ .*

Note that linear programs can be solved efficiently in $O(n^{3.5}L)$ time [6], where n is the number of variables and L is the number of input bits.

4 Extension to General Simple Paths

In the last section, we showed how to schematize a monotone path. Unfortunately, some routes in road networks are neither x - nor y -monotone, however, they can be decomposed into a (very) limited number of x - and y -monotone subpaths. So, we propose the following three-step heuristic to schematize general simple paths: We first split the input path (P, π) into a minimum number of x - or y -monotone subpaths (P_i, π_i) , where π_i equals π restricted to the subpath P_i . We embed each (P_i, π_i) separately according to Section 3. Then, we concatenate the subpaths such that the resulting path (P', ξ) is a simple \mathcal{C} -oriented path.

Note that this heuristic does not guarantee to preserve the orthogonal order between node pairs of different subpaths.

Splitting an embedded simple path $P = (v_1, \dots, v_n)$ into the minimal number k of subpaths $P_i, 1 \leq i \leq k$ with the property that each P_i is an x - or y -monotone path can be done in straightforward greedy fashion, starting from v_1 . We traverse P until we find the last vertices v' and v'' which are not violating the x - and y -monotonicity, respectively. If v' appears later than v'' on P , we set $P_1 = (v_1, \dots, v')$, otherwise $P_1 = (v_1, \dots, v'')$. We continue this procedure until we reach the end of P . This algorithm runs in $O(n)$ time and returns the minimal number k of x - or y -monotone subpaths.

After splitting the input path, we schematize each subpath (P_i, π_i) according to Section 3. We obtain a \mathcal{C} -oriented and orthogonal-order preserving embedding ρ_i with minimum schematization cost and minimum path length for each (P_i, π_i) . For concatenating these subpaths, we must solve the following problem.

Problem 2. Given a sequence of k embedded x - or y -monotone paths (P_i, ρ_i) with $1 \leq i \leq k$, find an embedding ξ of $P' = P_1 \oplus \dots \oplus P_k$, where \oplus denotes the concatenation of paths, such that

- (i) for each subpath (P_i, ξ_i) , the embedding ξ_i is a translation of ρ_i and
- (ii) (P', ξ) is a simple \mathcal{C} -oriented path.

Our approach is based on iteratively embedding the subpaths P_1, \dots, P_k . We ensure that in each iteration i the embedding of $P_1 \oplus \dots \oplus P_i$ remains conflict-free, i. e., it has no self-intersections. We achieve this by adding up to three new *path-link edges* between any two adjacent subpaths P_i and P_{i+1} . For each $1 \leq i \leq k$ let B_i denote the bounding box of (P_i, ρ_i) . A key operation of the algorithm is *shifting* a subpath P_i (or equivalently a bounding box B_i) by an offset $\Delta = (\Delta_x, \Delta_y) \in \mathbb{R}^2$. This is done by defining the lower left corner of each bounding box B_i as its origin o_i and storing the coordinates of P_i relative to o_i , i. e., $\xi(v) = o_i + \rho_i(v)$. Note that shifting preserves all local properties of (P_i, ρ_i) , i. e., the orthogonal order as well as edge lengths and orientations.

Each iteration of our algorithm consists of two steps. First, we *attach* the subpath P_i to its predecessor P_{i-1} . To that end, we initially place (P_i, ξ_i) such that the last vertex u of P_{i-1} and the first vertex v of P_i coincide. Then we add either two path-link edges (if the monotonicity directions of P_{i-1} and P_i are orthogonal) or three path-link edges (if P_{i-1} runs in the opposite direction of P_i) between u and v and shift B_i by finding appropriate lengths for the new edges such that $B_{i-1} \cap B_i = \emptyset$. Paths P_{i-1} and P_i are now conflict-free, but there may still exist conflicts between P_i and paths $P_j (j < i - 1)$. These are resolved in a second step that “pushes” any conflicting bounding boxes away from B_i by stretching some of the path-link edges.

Attaching a Subpath. Without loss of generality, we restrict ourselves to the case that P_{i-1} is an x -monotone path from left to right. Let u be the last vertex of P_{i-1} and v be the first vertex of P_i . If P_i is y -monotone we add a horizontal edge $e_1 = uv'$ with $\alpha_\xi(e_1) = 0^\circ$ connecting u to a new vertex u' . Then we also

Fig. 3: Two examples for attaching P_i to P_{i-1} by inserting path-link edges.

add a vertical edge $e_2 = u'v$ with $\alpha_\xi(e_1) = 90^\circ$ if P_i is upward directed and $\alpha_\xi(e_1) = 270^\circ$ if it is a downward path. Otherwise, if P_i is x -monotone from right to left, we add two vertices u' and u'' and three path-link edges $e_1 = uu'$, $e_2 = u'u''$, and $e_3 = u''v$ with $\alpha_\xi(e_1) = 0^\circ$, $\alpha_\xi(e_2) = 90^\circ$ if P_i is above P_{i-1} in π or $\alpha_\xi(e_2) = 270^\circ$ otherwise, and $\alpha_\xi(e_3) = 180^\circ$. Note that we treat each path-link edge as having its own bounding box with zero width or height. It remains to set the lengths of the path-link edges such that $B_i \cap B_j = \emptyset$ by computing the vertical and horizontal overlap of B_{i-1} and B_i . Figure 3 illustrates both situations.

Resolving Conflicts. After adding P_i we have $B_{i-1} \cap B_i = \emptyset$. However, there may still exist conflicts with any $B_j, 1 \leq j < i - 1$. In order to free up the space required to actually place B_i without overlapping any other bounding box, we push away all conflicting boxes in three steps. For illustration, let P_i be x -monotone from left to right, and let v be the first vertex of P_i . Each bounding box B is defined by its lower left corner $ll(B) = (ll_x(B), ll_y(B))$ and its upper right corner $ur(B) = (ur_x(B), ur_y(B))$. In the first step we identify the leftmost box B' (if any) that is intersected by a line segment that extends from $\xi(v)$ to the right with length equal to the width of B_i . For this box B' we have $ll_y(B') \leq y_\xi(v) \leq ur_y(B')$ and $ll_x(B_i) \leq ll_x(B') \leq ur_x(B_i)$. If there is such a B' let the offset be $\Delta_x = ur_x(B_i) - ll_x(B')$. Now we shift *all* bounding boxes B that lie completely to the right of $ll_x(B')$ to the right by Δ_x . All horizontal path-link edges (which are also considered bounding boxes by themselves) that connect a shifted with a non-shifted path are stretched by Δ_x to keep the two paths connected. Note that there is always a horizontal path-link edge between any two subsequent paths. Next, we inflate B_i , which is currently a horizontal line segment, downwards: we first determine the topmost conflicting box B'' (if any) below a horizontal line through $\xi(v)$, i. e., a box B'' whose x -range intersects the x -range of B_i and for which $ll_y(B_i) \leq ur_y(B'') \leq y_\xi(v)$. If we find such a B'' we define the vertical offset $\Delta_{y1} = ur_y(B'') - ll_y(B_i)$. We shift all bounding boxes B that lie completely below $ur_y(B'')$ downwards by Δ_{y1} . All vertical path-link edges that connect a shifted with a non-shifted box are stretched by Δ_{y1} in order to keep the two boxes connected. Again, there is always a vertical path-link edge between any two subsequent paths. Finally, we inflate B_i upwards, which is analogous to the downward inflation. Figure 4 shows an example and Theorem 4

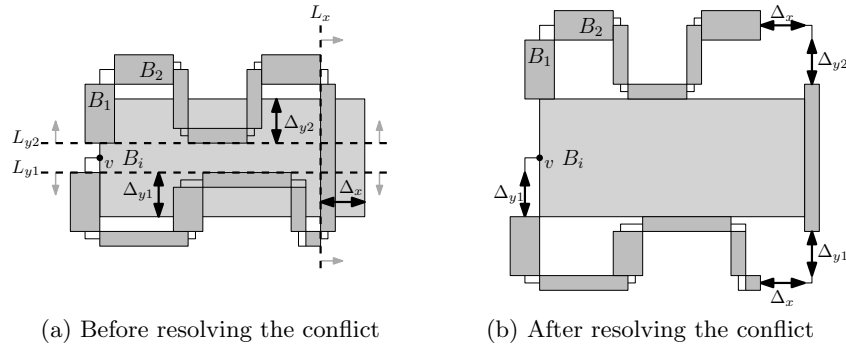

Fig. 4: Example for iteratively resolving conflicts induced by attaching P_i .

sums up the insights gained in this section. The proof and more details can be found in the full paper [4].

Theorem 4. *Our algorithm computes a solution (P', ξ) to Problem 2 by adding at most $3(k-1)$ path-link edges to P in $O(k^2 + n)$ time.*
